HyRiM-package

Multicriteria Risk Management using Zero-Sum Games with Vector-Valued Payoffs that are Probability Distributions

Description

Author(s)

Stefan Rass, Sandra Koenig, Ali Alshawish

Maintainer: "Stefan Rass, on behalf of the Austrian Institute of Technology" <stefan.rass@jku.at>

References

S. Rass, S. König, S. Schauer: Games over Probability Distributions Revisited: New Equilibrium Models and Refinements, MDPI Games 2022, 13(6), 80; DOI: https://doi.org/10.3390/g13060080, online: https://www.mdpi.com/2073-4336/13/6/80

cdf

(cumulative) loss distribution function

Description
returns the numeric values of the cumulative loss distribution \( ld \) evaluated at \( x \), i.e., \( \Pr(X \leq x) \), where \( X \sim ld \).

Usage
\[
cdf(ld, x)
\]

Arguments
- \( ld \) the loss distribution as obtained from \( \text{lossDistribution} \) or \( \text{mgss} \).
- \( x \) the point at which the distribution function shall be evaluated (must be a numeric; vectors are not supported yet)

Details
the function internally distinguishes discrete and continuous distributions only in terms of rounding its argument to the largest integer less than \( x \). Its value is obtained by numeric integration of the internal representation of the loss distribution (in the continuous case).

For discrete distributions, the function works on the internal probability mass function (which may be different from the empirical distribution in case that the loss distribution has been smoothed during its construction; see \( \text{lossDistribution} \)).

Value
an approximation for the probability \( \Pr(ld\leq x) \).

Note
in its current version, \( cdf \) does not vectorize, i.e., cannot be applied to vector arguments \( x \).
disappointmentRate

Author(s)
Stefan Rass

See Also
suitable inputs for this function are provided by lossDistribution and mgss.

Examples

```r
cvss1base <- c(10, 6.4, 9, 7.9, 7.1, 9)
ld <- lossDistribution(cvss1base)
cdf(ld, 4)
```

---

### Description

For a minimizing player, the **disappointment rate** is the likelihood for the loss to exceed its expectation (thus disappoint the defender). For any random loss $X$, it is given by $Pr(X > E(X))$.

### Usage

```r
disappointmentRate(d, x, y, verbose = TRUE, ...)
```

### Arguments

- **d**: a lossDistribution object or a matrix; typically the assurance from a previously computed equilibrium (see mgss). In that case, all other parameters are ignored. Alternatively, one can provide a matrix of real values instead, to compute the disappointment rate in the so-specified zero-sum matrix game. In that case, the other parameters are also taken into consideration.
- **x, y**: the mixed strategies under which the disappointment rate shall be computed. Usually, this would be an equilibrium of the (real-valued) matrix game. If only x or only y is supplied, the function computes a best response to the given (mixed) strategy. If both are omitted, the function internally computes an equilibrium by a call to mgss.
- **verbose**: if set to FALSE, suppresses all messaging.
- **...**: further parameters internally passed onwards to mgss to compute an equilibrium.

### Details

The disappointment rate can be taken as an auxiliary goal to optimize, though it is not supported for optimization in the current version of the package. Note that it does not make sense to consider this rate as an isolated (single) goal, since the optimal strategy would then be playing towards maximal losses (with explicit aid of the opponent) in order to minimize the mass to the left of the expected loss. However, it is a quantity of interest when the equilibrium has been computed, as it indicates how "satisfying" the equilibrium will be upon playing.
disappointmentRate

Value
the likelihood to overshoot the expectation of the random loss $X$ with distribution $d$, i.e., $P_r(X > E(X))$.

### lossDistribution

#### Description

Loss distributions can be constructed from both, continuous and categorical data. In any case, the input data must be a list (vector) of at least two numeric values all being \geq 1. For discrete data, the function additionally takes the full range of categories, all being represented as integers (with the lowest category having the number 1).

#### Usage

# construct a loss distribution from data
lossDistribution(
  dat,
  discrete = FALSE,
  dataType = c("raw", "pdf", "cdf"),
  supp = NULL,
  smoothing = c("none", "ongaps", "always"),

lossDistribution

bw = NULL)
# get information about the loss distribution
## S3 method for class 'mosg.lossdistribution'
print(x, ...)
## S3 method for class 'mosg.lossdistribution'
summary(object, ...)
## S3 method for class 'summary.mosg.lossdistribution'
print(x, ...)
## S3 method for class 'mosg.lossdistribution'
plot(x, points = 100, xlab = "", ylab = "",
     main = "", p = 0.999, newPlot = TRUE, cutoff = NULL, ...)
# get quantitative information about the distribution
## S3 method for class 'mosg.lossdistribution'
quantile(x, p, eps = 0.001, ...)
## S3 method for class 'mosg.lossdistribution'
mean(x, ...)
# evaluate the loss density function
## S3 method for class 'mosg.lossdistribution'
density(x, t, ...)
# for the cumulative distribution function, see the function 'cdf'

Arguments

dat a vector of at least two input observations (all \( \geq 1 \) required)
discrete defaults to FALSE. If set to TRUE, the loss distribution is constructed as discrete. In that case, a value for supp is required.
dataType applies only if discrete=TRUE, and specifies how the values in dat are to be interpreted. Defaults to raw, by which the data is taken as observations. Given as pdf, the values in dat are directly interpreted as a probability density (checked for nonnegativity and re-normalized if necessary). If the data type is specified as cdf, then the values in dat are taken as cumulative distribution function, i.e., checked to be non-decreasing, non-negative and re-normalized to 1 if necessary.
supp if the parameter discrete is set to TRUE, then this parameter must be set as a vector of two elements, specifying the minimal and maximal category, e.g. supp=c(1,5).
bw the bandwidth parameter (numeric value) for kernel smoothing. Defaults internally to the result of bw.nrd0 if omitted.
x a loss distribution object returned by lossDistribution or mgss, or a value within the support of a loss distribution.
t a value within the support of ld or a summary object for a loss distribution.
object a loss distribution object
eps the accuracy at which the quantile is approximated (see the details below).
smoothing string; partially matched with "none" (default), "ongaps", and "always". If set to "always", then the function computes a discrete kernel density estimate (using a discretized version of a Gaussian density with a bandwidth as computed by bw.nrd0 (Silverman’s rule)), to assign categories with zero probability a positive
lossDistribution

If set to "ongaps", then the smoothing is applied only if necessary (i.e., if the probability mass is zero on at least one category).

The function plot.mosg.lossdistribution takes the parameters:

- `points`: the number of points at which loss densities are is evaluated (numerically) for plotting.
- `xlab`: a label for the x-axis in the plot.
- `ylab`: a label for the y-axis in the plot.
- `main`: a title for the plot.
- `p`: a quantile that determines the plot range for the loss distribution.
- `newPlot`: if set to TRUE, then a new plot is opened. Otherwise, the plot is added to the current plot window (typically used by plot.mosg to visualize game matrices).
- `cutoff`: the cutoff point at which all densities shall be truncated before plotting (note that the mass functions are rescaled towards unit mass).
- `...`: further arguments passed to or from other methods.

Details

The function internally computes a Gaussian kernel density estimator (KDE; using Silverman’s rule of thumb for the bandwidth selection) on the continuous data. The distribution is truncated at the maximal observation supplied + 5*the bandwidth of the Gaussian KDE, or equivalently, at the right end of the support in case of discrete distributions.

For discrete distributions, missing observations are handled by smoothing the density (by convolution with a discretized Gaussian kernel). As an alternative, a re-definition of categories may be considered.

Degenerate distributions are not supported! The construction of classical games with real-valued payoffs works directly through mosg by supplying a list of values rather than loss distributions. See the example given with mosg.

The generic functions quantile, mean and density both distinguish discrete from continuous distributions in the way of how values are being computed.

Quantiles are computed using the direct definition as an approximation \( y \) so that \( x = \Pr(\text{ld} \leq y) \). For continuous distributions, a bisective search is performed to approximate the inverse cumulative distribution function. For discrete distributions, quantile works with cumulative sums. The accuracy parameter \( \varepsilon \) passed to quantile causes the bisective search to stop if the search interval has a length less than \( \varepsilon \). In that case, the middle of the interval is returned. For discrete distributions, the computation is done by cumulative sums on the discrete probability mass function.

Mean either invokes \( \text{moment}(\text{ld}, 1) \) to compute the first moment.

density is either a wrapper for the internal representation by the function object lossdistr, or directly accesses the probability mass function as internally stored in the field dpdf (see the 'values' section below).

For visualization, plot produces a bar plot for categorical distributions (over categories as specified by the supp field; see the 'values' section below), and for continuous distributions, a continuous line plot is returned on the range \( 1...\max(\text{range} + 5*\text{bw}) \), where the values are described below. To ease comparison and a visual inspection of the game matrix, the default plot ranges can be overridden by supplying xlim and ylim for the plot function.
lossDistribution

Value

The return values of lossDistribution is an object of class mosg.lossdistribution. The same goes for lossDistribution.mosg.

- **observations** carries over the data vector supplied to construct the distribution.
- **range** is the minimal and maximal loss observed, as a 2-element vector. For loss distributions induced by games, the range is the smallest interval covering the ranges of all distributions in the game.
- **bw** is the bandwidth used for the kernel density approximate.
- **lossdistr** is a function embodying the kernel density (probability mass function) as a spline function (for continuous densities only)
- **normalizationFactor** is the factor by which lossdistr must be multiplied (to normalize under the truncation at max(observations) + 5*bw.
- **is.mixedDistribution** is a flag indicating whether or not the distribution was constructed by a call to lossDistribution or the generic function lossDistribution.mosg.
- **is.discrete** is a flag set to TRUE if the distribution is over categories
- **dpdf** if is.discrete is TRUE, then this is a vector of probability masses over the support (field supp).
- **supp** if is.discrete is TRUE, then this is a 2-element vector specifying the minimal and maximal loss category (represented by integers).

A summary returns an object of class mosg.equilibrium.summary, for which the generic print function can be applied, and which carries the following fields:

- **range** is the minimal and maximal observation of the underlying data (if available), or the minimal and maximal losses anticipated for this distribution (e.g., in case of discrete distributions the common support).
- **mean** is the first moment as computed by mean.
- **variance** is the variance as computed by variance.
- **quantiles** is a 2x5-matrix of quantiles at levels 10%, 25%, 50%, 75% and 90%.

Note

If the plotting throws an error concerning too large figure margins, then adjusting the plot parameters using **par** may help, since the plot function does not override any of the current plot settings (e.g., issue par(c(0, 0, 1, 1) + 0.1)) before plotting to reduce the spacing close towards zero)

In some cases, plots may require careful customization to look well, so playing around with the other settings as offered by **par** can be useful.

If the distribution has been smoothed, then mean, variance, quantile, density and cdf will refer to the smoothed version of the distribution. In that case, the returned quantities are mere approximations of the analogous values obtained directly from the underlying data.

Author(s)

Stefan Rass
### Examples

```r
# construct a loss distribution from observations (raw data)
cvss1base <- c(10, 6.4, 9, 7.9, 7.1, 9)
ld <- lossDistribution(cvss1base)
summary(ld)
plot(ld)

# construct a loss distribution of given shape
# for example, a Poisson density with lambda = 4
x <- 1:10
f <- dpois(x, lambda = 4)
# construct the loss distribution by declaring the data
# to be a probability density function (pdf)
ld <- lossDistribution(f, dataType = "pdf", discrete = TRUE, supp = range(x))
# note that this call throws a warning since it internally
# truncates the loss distribution to the support 1:10, and
# renormalizes the supplied density for that matter.

# for further examples, see the documentation to 'mosg' and 'mosg.equilibrium'
```

---

**mgss**

**compute a multi-goal security strategy**

### Description

Finds security strategy that assures a maximal loss w.r.t. all goals of the given game, delivering a Pareto-efficient loss bound. Internally, it constructs an auxiliary one-against-all game and uses a sequence of linear programs to compute a lexicographic Nash equilibrium therein (Rass et al., 2022), using the methods described by (Lozovanu et al 2005; Rass, Wiegele & König 2020).

### Usage

```r
mgss(G, weights, cutOff, ord = 5, fbr = FALSE, points = 512, tol = 0.0)
```

### Arguments

- **G**
  - a multi-objective game constructed using moag
- **weights**
  - each goal in G can be assigned a weight to reflect its priority. If missing, the weights default to be all equal. The weights do not need to sum up to 1 (and are normalized towards a unit sum otherwise), but need to be all non-negative.
- **cutOff**
  - (only used for continuous loss distributions) the maximal loss for which no events are expected or otherwise the risk of exceeding cutOff are accepted. If missing, this value defaults to the maximal observation on which the loss distributions were constructed (equivalently, the right end of their common support).
ord

the order up to which a continuous loss distribution shall be approximated. This value may be set to high orders when it is necessary to distinguish distributions that are similar at the tails.

fbr

if set to `TRUE`, instruct the function to additionally compute the best replies regarding each goal individually, assuming that defender plays `optimalDefense` as a leader, and the attacker per goal follows (follower’s best reply). These replies are always pure strategies.

points

the number of points at which the resulting equilibrium loss distributions are evaluated numerically.

tol

occasionally, it was observed that the internal linear programs failed due to roundoff errors; in these cases, the function reported an "internal error" on the LP failure. In that case, one can supply a tolerance to go into the optimization to avoid such roundoff problems. By default, the tolerance is set to zero, to search for an "exact" solution, though. The GLPK status given in the error message refers to the codes for the GNU Linear Programming Kit, given at https://rdrr.io/cran/glpkAPI/man/glpkConstants.html.

Details

For continuous loss distributions, the function uses a Gaussian kernel density approximation (constructed using the function `lossDistribution`), and computes a Taylor-polynomial approximation at the $x$ equal to `cutOff` for each distribution up to order `ord`. Preferences are decided using the methods described by (Rass, König and Schauer; 2022), and (Rass, König, Schauer, Bürgin, Epperlein and Wirth; 2021), using sign-alternating derivatives, representing a distribution by a vector with `ord` elements. Categorical distributions are represented likewise directly by the vector of their probability masses. In both cases, preferences are decided by a lexicographic comparison of vector-representations. The returned optima are Nash equilibria for single-goal games, and lexicographic Nash equilibria for multi-goal games. Constructing a game using `mosg` with vectors in the payoff description can, consequently, allows to use `mgss` to compute optimal results with explicit goal priorities in multi-criteria games.

Value

An object of class `mosg.equilibrium`, containing the following fields:

`optimalDefense` a discrete probability distribution over the action space of player 1 (defender)

`optimalAttacks` a discrete probability distribution over the action space of player 2 (attacker). Note that this is not a best-response to the player 1’s `optimalDefense`, but rather the best that the attacker could do if the game were just about the particular goal that the attacker refers to. This worst-case scenario assumes that the defender would focus all its efforts to that single goal.

`assurances` a list of loss distributions valid under the assumption that player 1 adheres to the `optimalDefense` distribution in its randomized action choices, while the opponent plays its own zero-sum equilibrium strategy in the game that is only (and exclusively) about this particular goal. This value has to be interpreted with care, as it assumes that player 1 would put all efforts into a defense for the particular goal, but in reality, will have multiple criteria to simultaneously optimize. This means that the attacker, in turn, could adapt to the `optimalDefense` of player 1,
to cause more damage. The given assurance is thus only an upper bound of the worst-possible damage, under the assumption that player 1 would focus only on this particular goal.

The list can be accessed by the names for each goal as specified through the input mosg object G. Each distribution within assurances is a mixed loss distribution constructed using lossDistribution

\[ \text{br_to_optimalDefense} \]

This is a vector of best replies per goal for a leading defender playing the fixed strategy optimalDefense, and letting the adversary (player 2) follow. It is the (stochastically largest) damage among \( \text{optimalDefense}^T \cdot A_p \), when \( A_p \) is the game structure for the \( p \)-th goal; the vector \text{br_to_optimalDefense} contains the indices of the individually best replies, pointing into the list of attack strategies.

Note

The output loss distributions (accessible by the list assurances) cannot be used to construct a subsequent game (see mosg), since continuous distributions are represented as a sequence of points, rather than raw data or probability masses.

As of version 2.0.0 of the package, this function is no longer downwards compatible to earlier versions of itself, since the method of computation (formerly fictitious play) was replaced by linear programming to give exact solutions rather than approximations. Consequently, the parameters \( T \) (iteration count) and \( \varepsilon \) (accuracy) have become useless and have been removed after version 1.0.4.

---

**moment**

**compute moments of loss distributions**

**Description**

the moment of given order k is computed by numeric integration or summation (in case of discrete distributions)

**Usage**

moment(ld, k)

**Arguments**

- **ld**
  the loss distribution as obtained from lossDistribution or mgss.
- **k**
  the order of the moment (must be an integer \( \geq 1 \))

**Value**

the k-th order moment of the given loss distribution

**Note**

In case of continuous distributions, the value returned is an approximation and based on the internal kernel density approximation.

For categorical distributions, the function works on the internal probability mass function (which may be different from the empirical distribution in case that the loss distribution has been smoothed during its construction; see lossDistribution).

In its current version, cdf does not vectorize, i.e., cannot be applied to vector arguments x.
mosg

Stefan Rass

**See Also**

the methods `mean` and `variance` are based on this function.

**Examples**

```r
cvss1base <- c(10, 6.4, 9, 7.9, 7.1, 9)
ld <- lossDistribution(cvss1base)
cdf(ld, 4)
```

---

### Construction and handling of multi-objective security games

**Description**

this function takes a list of loss distributions constructed using `lossDistribution`, along with a specification of the game’s shape (number of strategies for both players and number of goals for the first player), and returns an object suitable for analysis by `mgss` to compute a multi-goal security strategy.

**Usage**

```r
mosg( n,
m,
goals,
losses,

```
# construct a loss distribution by playing a given strategy in the game G
## S3 method for class 'mosg'
lossDistribution(G, player1Strat, player2Strat, points = 512, goal = 1)

**Arguments**

- `n`: number of defense strategies (cardinality of the action space for player 1)
- `m`: number of attack strategies (cardinality of the action space for player 2)
- `goals`: number of goals for player 1 (must be ≥ 1)
- `losses`: a list with `n*m*goals` entries, which specifies a total of `goals` game matrices, each with shape `n`-by-`m`. The way in which the game matrices are filled from this list is controlled by the parameter `byrow`. Note that in every case, it is assumed that one matrix is specified after the other in the list.

Furthermore, the function assumes all loss distributions having a common support. This is only explicitly verified for discrete distributions (with errors reported), but implicitly assumed to hold for continuous distributions without further checks.

Typically, a game will be constructed from a list of loss distributions obtained by invocations of `lossDistribution`.

Games can be defined with real-valued (scalar) payoffs if a list of numbers is provided instead. Internally, the function converts these numbers into Bernoulli distributions; a scalar payoff `a` is converted into a Bernoulli random variable `X` having `Pr(X = a) = p ∝ a`. This conversion is equivalent to an invocation of `lossDistribution` with the parameters `dat=c(1-p, p), discrete=TRUE, dataType="pdf", smoothing="none", bw = 1` and `supp=c(1,2)`.

If the list of losses comes as a list of vectors, `mosg` will construct a game assuming a lexicographic order on the loss vectors (with the order being determined from left to right along the coordinates). To this end, `mosg` checks for all loss vectors to have the same length (otherwise, an error is reported). Negative and zero values in the loss vector are allowed.

- `byrow`: by default (TRUE), the game matrices are filled row-by-row from list `losses`. If set to FALSE, then the game matrices are filled column-by-column.

- `goalDescriptions`: if specified, this can be any vector (e.g., textual descriptions) for the goals. Defaults to 1, 2, 3, ... if missing. The length must be equal to `goals`.

- `defensesDescr`: if specified, this can be any vector (e.g., textual descriptions) for the defense strategies. Defaults to 1, 2, 3, ... if missing. The length must be equal to `n`.

- `attacksDescr`: if specified, this can be any vector (e.g., textual descriptions) for the attack strategies. Defaults to 1, 2, 3, ... if missing. The length must be equal to `m`.

- `x`: a game, object of class "mosg", as constructed by the function `mosg`.

The function `plot` additionally takes the following parameters:

- `goal`: an integer referring to the goal of interest (for plotting or to construct a loss distribution for). Defaults to the first goal if omitted.
points The number of points at which the density is evaluated (for continuous losses); this parameter is ignored for categorical losses.
cutoff the cutoff point at which all densities shall be truncated before plotting (note that the mass functions are rescaled towards unit mass). The plot function overrides the following settings internally (so supplying these as parameters will raise an error): xlab, ylab, main, type, names.arg and font.main (applying differently for bar and line plots)

largeGame if the plot exits with the error "figure margins too large", one can set this parameter to TRUE, causing plot to write to a temporary SVG file (scalable vector graphics), to avoid the figure space issue and hence the error. The price is a (potentially much) slower plotting, since the system creates the file, and loads it afterwards from the harddisk (cleaning up the file after displaying it).

subPlotWidth the width in inches for each payoff distribution in the game matrix. This parameter is ignored when largeGame is set to FALSE (the default).
subPlotHeight the height in inches for each payoff distribution in the game matrix. This parameter is ignored when largeGame is set to FALSE (the default).
cleanUp If the graph is to be used in other programs, one can supply cleanUp = FALSE to retain the temporary SVG file for subsequent use and prints a message where to find the file. By default, the temporary file gets deleted.

G a game constructed by mosg to deliver the loss distribution through its game matrices.
player1Strat a discrete distribution over the action space for the defending player 1 in the game G
player2Strat a discrete distribution over the action space for the attacking player 2 in the game G

Details

Upon input, the function does some consistency checks, such as testing the length of the parameter losses to be equal to n*m*goals. The loss distributions are checked for mutual consistency in terms of all being continuous or all being discrete (a mix is not allowed), and all being not mixed distributions (that is, the output distribution of a previous call to mgss cannot be used as input to this function).

The functions print.mosg gives a brief overview of the game, listing only the shape and strategies for both players. For detailed information, use summary on a specific loss distribution in the list for the game (field losses).

For plotting games, plot.mosg constructs an (n x m)-matrix of loss distributions with rows and columns in the grid being labeled by the values in defensesDescr and attacksDescr. The plot heading is the name for the specified goal. The function makes no changes to the plot parameters, so fine tuning can be done by changing the settings using the par function.
The function `lossDistribution.mosg` can be used to compute the distribution $x^T \star A \star y$, for the payoff distribution matrix $A$, and mixed strategies $x$ (player1strat) and $y$ (player2strat) in the game. The computation is by a pointwise addition of loss distributions, with the number of points being specifiable by the parameter points, which defaults to 512.

**Value**

The function returns an object of class `mosg`, usable with the function `mgss` to determine a security strategy (i.e., a lexicographic Nash equilibrium assuming a zero-sum one-against-all competition). The fields returned in the `mosg` object are filled with the input values supplied. In detail, the fields are:

- `nDefenses` the value of the parameter $n$
- `nAttacks` the value of the parameter $m$
- `dim` the value of the parameter goals
- `attacksDescriptions, defensesDescriptions, goalDescriptions` if supplied, then these are filled with the values of `goalDescr`, `defensesDescr` and `attacksDescr`; otherwise, they contain the default values described above.
- `maximumLoss` the maximal loss taken over all specified loss distributions
- `loc` a locus-function for accessing the list `losses` using a triple notation (goal,i,j), where goal addresses the game matrix and i,j are the row and column indices (starting from 1 as the smallest index). This function is used internally (only).

**Warning**

Games constructed with real-valued payoffs or payoff vectors over the reals are allowed with negative or zero values in the list of losses. In that case, embeds the loss values or vector into a `lossDistribution` object after shifting and scaling the values into the strictly positive range. This operation creates a strategically equivalent game, i.e., leaves the set of equilibria unchanged, yet the resulting `mosg` object is not useful with the `lossDistribution.mosg`, `moment`, `cdf`, or any other member functions for `lossDistribution` objects obtained from equilibria. Those have to be computed manually. Be aware that there will be no warnings issued whatsoever in that case of misuse, since the `lossDistribution` objects constructed to carry the real or vector-valued payoffs of the original game carry no information about the semantics of the values or vectors that they have been created from. Hence, the computation of equilibria works correctly using `mosg`, while any further analysis (including plots) needs to be done manually.

**Note**

It is important to remark that player 1 is always minimizing. To treat a maximizing player, one must reconstruct the game using regrets instead of losses, i.e., if the data for a specific loss distribution is $D$, then the game for a maximizing player 1 must be constructed from $(\max(D) - D)$ instead of $D$.

**Author(s)**

Stefan Rass
See Also

Security strategies for a `mosg` object can be obtained by calling `mgss`. The game itself can be constructed from the output of `lossDistribution`.

attacksDescr = c("a1", "a2"))

print(G)
summary(G)
plot(G)

# construct and solve scalar valued (classical) game;
# losses are all numbers (degenerate distributions)
# the resulting matrix game has the payoff structure:
```
mosg.equilibrium embodies all information related to a lexicographic Nash equilibrium computed by the function mgss.

Description

The generic functions print and summary provide brief, and detailed information about the lexicographic Nash equilibrium. The generic function plot can be used to visualize the equilibrium.

Usage

```r
## S3 method for class 'mosg.equilibrium'
summary(object, ...)  
## S3 method for class 'mosg.equilibrium.summary'
print(x)  
## S3 method for class 'mosg.equilibrium'
print(x, extended=FALSE, ...)  
## S3 method for class 'mosg.equilibrium'
plot(x, points=100, ...)  
```

Arguments

- **x** an mgss object as returned by the function mgss.
- **object** an mgss object as returned by the function mgss.
  for print.mosg.equilibrium, the following parameter can be supplied:  
  - **extended** if set to TRUE, then the individual assurances are printed as well.
  for plot.mosg.equilibrium, the following parameter can be supplied:  
  - **points** the number of points to evaluate the density function over its support for plotting  
  - **...** further arguments passed to or from other methods.

Value

the result returned by the function summary carries the following fields:

- **optimalDefense** a discrete probability distribution over the action space for player 1 (the defender).
- **optimalAttacks** a discrete probability distribution over the action space for player 2 (the attacker).
assurances an optimal loss distribution valid under the assumption that the defender plays
optimalDefense as its mixed strategy. This is a list of mosg.lossdistribution
objects, accessible through their assigend names (coming from the underlying
game) or by indices.

The action spaces for both players are defined in first place by the game for which the equilibrium
was computed (via mgss on a game constructed by mosg).

print gives a shortened output restricted only to displaying the optimal defense for the defender
and attack strategies per goal (as defined by the underlying game).

summary returns an object of class summary.mosg.lossdistribution, which has the fields: "range"
"mean" "variance" "quantiles" "is.discrete"

range the minimal and maximal values of the loss (as anticipated by the observations)
mean the first moment as computed by mean
variance the variance as computed by variance
quantiles a 2x5-matrix of quantiles at the 10%,25%,50%,75% and 90% level
is.discrete a Boolean flag being TRUE if the loss distribution is over categories

plot displays a grid of plots, starting with the optimal defense behavior plotted as a discrete
distribution on top of a (m x 2)-matrix of plots. Each line in this grid shows the discrete optimal
attack strategy on the right side (as a bar plot), paired with the loss distribution (extracted from
x) caused when the defender plays optimalDefense and the attacker plays the respective optimal
attack strategy.

## compute payoff densities
preference

Decision on preferences between loss distributions

Description

This function implements the total ordering on losses, based on treating the moment sequences as hyperreal numbers, and returns the lesser of the loss distribution representatives in the hyperreal space.

Usage

preference(x, y, verbose = FALSE, weights, points = 512)

Arguments

x a loss, being either a number, a distribution or list of distributions (objects of class mosg.lossdistribution)

y a loss, being either a number, a distribution or list of distributions (objects of class mosg.lossdistribution)
weights a vector of \( n = \text{length}(x) = \text{length}(y) \) nonzero numbers (not necessarily summing up to 1), used only if \( x \) and \( y \) are lists of \text{mosg.lossdistribution} objects corresponding to \( n > 1 \) goals. In that case, the \( i \)-th goal gets assigned the weight (priority) \text{weights}[i]. Defaults to all goals having equal priority if the parameter is missing (\text{weights} \equiv \text{rep}(1/\text{length}(x), \text{length}(x))).

verbose if set to \text{TRUE}, the function returns the preferred of its arguments directly (thus, giving back \( x \) or \( y \)). If set to \text{FALSE} (default), then it returns the argument index (1 = \( x \), 2 = \( y \)) or 0 in case that \( x = y \).

points the number of points at which the distributions are evaluated numerically to determine the preference.

Details

Deciding the preference ordering defined in terms of moment sequence as proposed in (Rass, 2015). To avoid having to compute all moments up to an unknown order, this function decides by looking at the tails of the distribution, returning the one with faster decaying tail as the preferred distribution. This method delivers exact decisions for discrete distributions, but is only an approximate approach for continuous densities.

Value

the result is either a copy of the input parameter \( x \) or \( y \), depending on which distribution is preferred.

Computes the approximate variance of a loss distribution.

Description

The computation is based on Steiner’s theorem $\text{var}(X) = \mathbb{E}(X^2) - (\mathbb{E}(X))^2$, where the respective first and second moments are computed using the moment function (from this package). Internally, these functions operate on the approximate kernel density estimation for both, continuous and categorical distributions (see the lossDistribution function for details).

Usage

variance(x)

Arguments

x an object of class mosg.lossDistribution

Value

the approximate variance value

Note

the function works on the internal probability mass function (which may be different from the empirical distribution in case that the loss distribution has been smoothed during its construction; see lossDistribution). The function delivers only an approximate variance, whose error is due to numeric roundoff errors (known to occur in Steiner’s formula), and the fact that the computation is done on an approximate density (rather than the empirical distribution).

`.mosg`  
*Extract or replace parts of a game’s payoff matrix*

**Description**

Construct a new game by taking out a specified set of rows, columns and goals from a given game `G`. The new game inherits all descriptions (rows, cols and goals) from the `G`, and has its list of loss distributions organized in the same way (by rows or columns) as `G`.

The extraction or substitution works like as for data frames (see [.data.frame]). Strategies for both players, as well as goals, can equivalently be addressed by their string-names.

**Usage**

```r
## S3 method for class 'mosg'
x[i,j,k=NULL]
```

```r
## S3 replacement method for class 'mosg'
x[i,j,k=NULL] <- value
```

**Arguments**

- `x` a game of class `mosg`
- `i,j,k` a numeric value or numeric vector of row incides `i`, column indices `j`, or goals `k`.
- `value` a list of `lossDistribution` objects, or a game object of class `mosg`.

**Details**

For `[ extraction of elements from a payoff matrix, omitting any index dimension selects all elements in the respective dimension. Supplying negative values excludes the respective elements. For example, `G[c(1:3), 1]` returns a game with only the rows 1..3 of `G`, but all column strategies that `G` had, and only the first of `G`’s goals retained.

For `[<-, the list of substitute values needs to be of the same length as the number of elements addressed by the triple `(i,j,k)`, otherwise an error is returned. If the new elements come from another game object, say `G2`, only the loss distributions get replaced, but not the names of the strategies. The replacement checks if `G2` has its list of loss distributions organized in the same way as `G`, i.e., row-by-row or column-by-column. If there is a mismatch, the substitution is nonetheless done, but a warning about this issue is printed.

**Value**

`[` returns a freshly constructed game object.
Warning

For [<-, be aware that the replacement does not semantically check if the newly incoming loss distributions make sense as elements of the new game (e.g., they can have different supports, or be discrete/continuous while the game was continuous/discrete in its payoffs). Respective errors may only subsequently come up when the modified or extracted game is used.
